

(possibly incomplete list of)

Topics Covered in Sections 8.6, 10.1-10.2 and Chapter 11

Section 8.6 - Power

Power (how to use a power curve, not how to calculate one)

How changing α and the sample size affect the power

Sections 10.1-10.2 - One-way Analysis of Variance

The null and alternate hypothesis for one-way analysis of variance

The assumptions for the one-way ANOVA are the same as for a two-sample t-test: samples are random and independent (need to know how it was sampled), the populations are normally distributed (make a separate q-q plot for each group), that the variances of the populations are the same (use side by side box-plots or calculate the standard deviations)

How the ANOVA table is constructed for the one-way analysis of variance

$MS = SS/df$

$MSB = MST$ is based on the variance between the treatment averages

$MSW = MSE$ is based on the variance within each group separately

TMS is the variance of all the data points ignoring they are from separate groups

If the assumptions are met we can use the MS to construct an F test

How the F is constructed from the MS, and what null and alternate hypotheses it tests

That we reject the null hypothesis when the F statistic is large

Using the formulas for the SS to construct the ANOVA table

Finding the mean squares given the sum of squares and degrees of freedom

How the degrees of freedom are found

for total and error/within it is the sample size minus the number of parameters estimated

for the treatment/between it is the number of treatments minus 1

For two-samples, the one-way ANOVA and the two-sample t-test (with equal variances) give the same p-value and that $F=t^2$

Why we need the y_{ij} notation

How we can check the assumptions for one-way ANOVA using the residual vs. predicted plot and the q-q plot of the residuals

Chapter 11 - Linear Regression

The regression model equation (as given in the middle of page 512)

The four assumptions for linear regression (as given on pages 529-530)

Independent vs. dependent variable

Correlation vs. Causality

Extrapolation

The estimates of β_0 and β_1 are gotten by minimizing the sum of the squared residuals (SSE)

What is meant by regression to the mean

The analysis of variance table

TSS is the total amount of error/variation in Y

SSR = TSS - SSE is the amount of error/variation we explained by using the regression line

MSE is the estimated variance (σ^2) of the points around the regression line

Because we assumed the residuals are normal we can use the MS to do an F test

Finding the mean squares given the sum of squares and degrees of freedom

How the degrees of freedom are found

for total and error it is the sample size minus the number of parameters estimated

for the regression it is df for the total minus the df for the error

$F = MSR/MSE$

When we accept or reject $\beta_1 = 0$ based on the ANOVA table

Using the formulas for the SS to construct an ANOVA table

How the MS relate to the variances of the normal distributions in figures like 11.7 (page 530)

The t-test and confidence interval for β_1 (section 11.5)

The range of values the correlation coefficient can take.

The correlation as a single number summary of regression: with sample size it determines the F-statistic, $r^2 =$ coefficient of determination = percent of variation/error explained by the model, and r is like the slope of the regression line after adjusting for the scale of y and x .

What to look for in residual plots: is there a pattern in the residual vs. predicted plot? (violation of mean 0), is there a "funnel shape" in the residual vs. predicted plot? (error variances are not constant), does the q-q plot look like a straight line? (are the errors normal)
