## Chapter 5 - Logistic Regression I

The logistic regression model is
$Y_{i} \sim \operatorname{bin}\left(n_{i}, \pi_{i}\right), \quad \pi_{i}=\frac{\exp \left(\beta_{0}+\beta_{1} x_{i 1}+\cdots+\beta_{p-1} x_{i, p-1}\right)}{1+\exp \left(\beta_{0}+\beta_{1} x_{i 1}+\cdots+\beta_{p-1} x_{i, p-1}\right)}$.

- $\mathbf{x}_{i}=\left(1, x_{i 1}, \ldots, x_{i, p-1}\right)$ is a $p$-dimensional vector of explanatory variables including a place holder for the intercept.
- $\boldsymbol{\beta}=\left(\beta_{0}, \ldots, \beta_{p-1}\right)$ is the $p$-dimensional vector of regression coefficients. These are the unknown population parameters.
- $\eta_{i}=\mathbf{x}_{i}^{\prime} \boldsymbol{\beta}$ is called the linear predictor.
- Page 163: many, many uses including credit scoring, genetics, disease modeling, etc, etc...
- Many generalizations: ordinal data, complex random effects models, discrete choice models, etc.

### 5.1.1 Model interpretation

Lets start with simple logistic regression:

$$
Y_{i} \sim \operatorname{bin}\left(n_{i}, \frac{e^{\alpha+\beta x_{i}}}{1+e^{\alpha+\beta x_{i}}}\right) .
$$

An odds ratio: let's look at how the odds of success changes when we increase $x$ by one unit:

$$
\begin{aligned}
\frac{\pi(x+1) /[1-\pi(x+1)]}{\pi(x) /[1-\pi(x)]} & =\frac{\left[\frac{e^{\alpha+\beta x+\beta}}{1+e^{\alpha+\beta x+\beta}}\right] /\left[\frac{1}{1+e^{\alpha+\beta x+\beta}}\right]}{\left[\frac{e^{\alpha+\beta x}}{1+e^{\alpha+\beta x}}\right] /\left[\frac{1}{1+e^{\alpha+\beta x}}\right]} \\
& =\frac{e^{\alpha+\beta x+\beta}}{e^{\alpha+\beta x}}=e^{\beta} .
\end{aligned}
$$

When we increase $x$ by one unit, the odds of an event occurring increases by a factor of $e^{\beta}$, regardless of the value of $x$.

## Another interpretation for $\beta$

So $e^{\beta}$ is an odds ratio.
We also have

$$
\frac{\partial \pi(x)}{\partial x}=\beta \pi(x)[1-\pi(x)]
$$

Note that $\pi(x)$ changes more when $\pi(x)$ is away from zero or one than when $\pi(x)$ is near 0.5.

This gives us approximately how $\pi(x)$ changes when $x$ increases by a unit. This increase depends on $x$, unlike the odds ratio.
See Figure 5.1, p. 164.

### 5.1.3 Horseshoe crab data

Let's look at $Y_{i}=1$ if a female crab has one or more satellites, and $Y_{i}=0$ if not. So

$$
\pi(x)=\frac{e^{\alpha+\beta x}}{1+e^{\alpha+\beta x}}
$$

is the probability of a female having more than her nest-mate around as a function of her width $x$.

```
data crabs;
input color spine width satell weight @@; weight=weight/1000; color=color-1;
y=0; if satell>0 then y=1;
datalines;
...DATA HERE...
```

## Fit of $\log i t\left(\pi_{i}\right)=\alpha+\beta x_{i}$ where $x_{i}$ is width

We estimate the probability of a satellite as

$$
\hat{\pi}(x)=\frac{e^{-12.35+0.50 x}}{1+e^{-12.35+0.50 x}}
$$

The odds of having a satellite increases by a factor between 1.3 and 2.0 times for every cm increase in carapace width.

The coefficient table houses estimates $\hat{\beta}_{j}$, $\operatorname{se}\left(\widehat{\beta}_{j}\right)$, and the Wald statistic $z_{j}^{2}=\left\{\hat{\beta}_{j} / \operatorname{se}\left(\hat{\beta}_{j}\right)\right\}^{2}$ and $p$-value for testing $H_{0}: \beta_{j}=0$. What do we conclude here?

### 5.1.2 Looking at data

With a single predictor $x$, can plot $p_{i}=y_{i} / n_{i}$ versus $x_{i}$. This approach works well when $n_{i} \neq 1$. The plot should look like a "lazy s." Alternatively, the sample logits
$\log p_{i} /\left(1-p_{i}\right)=\log y_{i} /\left(n_{i}-y_{i}\right)$ versus $x_{i}$ should be approximately straight. If some categories have all successes or failures, an ad hoc adjustment is $\log \left\{\left(y_{i}+0.5\right) /\left(n_{i}-y_{i}+0.5\right)\right\}$.
When many $n_{i}$ are small, you can group the data yourself into, say, 10-20 like categories and plot them. For the horseshoe crab data let's use the categories defined in Chapter 4. A new variable $w$ is created that is the midpoint of the width categories:

```
data crab1; input color spine width satell weight;
    weight=weight/1000; color=color-1;
    y=0; n=1; if satell>0 then y=1; w=22.75;
    if width>23.25 then w=23.75;
    if width>24.25 then w=24.75;
    if width>25.25 then w=25.75;
    if width>26.25 then w=26.75;
    if width>27.25 then w=27.75;
    if width>28.25 then w=28.75;
    if width>29.25 then w=29.75;
```

## Plot of sample logits vs. width windows

```
proc sort data=crab1; by w;
proc means data=crab1 noprint; by w; var y n; output out=crabs2 sum=sumy sumn;
data crabs3; set crabs2; p=sumy/sumn;
logit=log((sumy+0.5)/(sumn-sumy+0.5));
proc gplot;
    plot p*w; plot logit*w;
```

Figure: Sample logits versus width; is this "straight?"

## Another option is to use loess

- loess (Cleveland, 1979) stands for locally weighted scatterplot smoothing.
- For data $\left\{\left(x_{i}, y_{i}\right)\right\}_{i=1}^{n}$, a weighted regression is fit at each $x_{0}$, where $x$-values further away from $x_{0}$ are given less weight.
- Essentially fits a nonparametric mean function $\mu(x)=E(y \mid x)$ to $\left\{\left(x_{i}, y_{u}\right)\right\}_{i=1}^{n}$.
- Useful for (a) exploratory visualization of data, e.g. "is the mean approximately a line?" and (b) residual plots for models where the response is binary or a count.
- However, loess does not restrict the mean to be between zero and one!
proc sgscatter;
plot y*width / loess;

### 5.1.4 Retrospective sampling \& logistic regression

In case-control studies the number of cases and the number of controls are set ahead of time. It is not possible to estimate the probability of being a case from the general population for these types of data, but just as with a $2 \times 2$ table, we can still estimate an odds ratio $e^{\beta}$.

Let $Z$ indicate whether a subject is sampled $(1=y e s, 0=n o)$. Let $\rho_{1}=P(Z=1 \mid y=1)$ be the probability that a case is sampled and let $\rho_{0}=P(Z=1 \mid y=0)$ be the probability that a control is sampled.

In a simple random sample, $\rho_{1}=P(Y=1)$ and
$\rho_{0}=P(Y=0)=1-\rho_{1}$.
Assume the logistic regression model

$$
\pi(x)=P\left(Y_{i}=1 \mid x\right)=\frac{e^{\alpha+\beta x}}{1+e^{\alpha+\beta x}}
$$

## Case-control studies, cont.

Assume that the probability of choosing a case is independent of $x$, $P(Z=1 \mid y=1, x)=P(Z=1 \mid y=1)$ and the same for a control $P(Z=1 \mid y=0, x)=P(Z=1 \mid y=0)$. This is the case, for instance, when a fixed number of cases and controls are sampled retrospectively, regardless of their $x$ values.

Bayes' rule gives us

$$
\begin{aligned}
P(Y=1 \mid z=1, x) & =\frac{\rho_{1} \pi(x)}{\rho_{1} \pi(x)+\rho_{0}(1-\pi(x))} \\
& =\frac{e^{\alpha^{*}+\beta x}}{1+e^{\alpha^{*}+\beta x}}
\end{aligned}
$$

where $\alpha^{*}=\alpha+\log \left(\rho_{1} / \rho_{0}\right)$.
The parameter $\beta$ has the same interpretation in terms of odds ratios as with simple random sampling.

## Comments

- This is very powerful \& another reason why logistic regression is widely used.
- Other links (e.g. identity, probit) do not have this property.
- Matched case/controls studies require more thought; Chapter 11.
- 5.1.5 relates directly to ROC analysis where $x$ is a diagnostic test score (e.g. ELISA) and $Y$ indicates presence/absence of disease.

### 5.2.1 Inferences for regression effects

Consider the full model

$$
\operatorname{logit}\{\pi(\mathbf{x})\}=\beta_{0}+\beta_{1} x_{1}+\cdots+\beta_{p-1} x_{p-1}=\mathbf{x}^{\prime} \boldsymbol{\beta}
$$

Most types of inferences are functions of $\boldsymbol{\beta}$, say $g(\boldsymbol{\beta})$. Some examples:

- $g(\boldsymbol{\beta})=\beta_{j}, j^{\text {th }}$ regression coefficient.
- $g(\boldsymbol{\beta})=e^{\beta_{j}}, j^{\text {th }}$ odds ratio.
- $g(\boldsymbol{\beta})=e^{\mathrm{x}^{\prime} \boldsymbol{\beta}} /\left(1+e^{\mathrm{x}^{\prime} \boldsymbol{\beta}}\right)$, probability $\pi(\mathbf{x})$.

If $\hat{\boldsymbol{\beta}}$ is the MLE of $\boldsymbol{\beta}$, then $g(\hat{\boldsymbol{\beta}})$ is the MLE of $g(\boldsymbol{\beta})$. This provides an estimate.

The delta method is an all-purpose method for obtaining a standard error for $g(\hat{\boldsymbol{\beta}})$.

## Delta method

We know

$$
\hat{\boldsymbol{\beta}} \dot{\sim} N_{p}(\boldsymbol{\beta}, \widehat{\operatorname{cov}}(\hat{\boldsymbol{\beta}}))
$$

Let $g(\boldsymbol{\beta})$ be a function from $\mathbb{R}^{p}$ to $\mathbb{R}$. Taylor's theorem implies, as long as the MLE $\hat{\boldsymbol{\beta}}$ is somewhat close to the true value $\boldsymbol{\beta}$, that

$$
g(\boldsymbol{\beta}) \approx g(\hat{\boldsymbol{\beta}})+[D g(\hat{\boldsymbol{\beta}})](\boldsymbol{\beta}-\hat{\boldsymbol{\beta}})
$$

where $[\operatorname{Dg}(\boldsymbol{\beta})]$ is the vector of first partial derivatives

$$
D g(\boldsymbol{\beta})=\left[\begin{array}{c}
\frac{\partial g(\boldsymbol{\beta})}{\partial \beta_{1}} \\
\frac{\partial g(\boldsymbol{\beta})}{\partial \beta_{2}} \\
\vdots \\
\frac{\partial g(\boldsymbol{\beta})}{\partial \beta_{p}}
\end{array}\right]
$$

## Delta method

Then

$$
(\hat{\boldsymbol{\beta}}-\boldsymbol{\beta}) \dot{\sim} N_{p}(\mathbf{0}, \widehat{\operatorname{cov}}(\hat{\boldsymbol{\beta}})),
$$

implies

$$
[D g(\boldsymbol{\beta})]^{\prime}(\hat{\boldsymbol{\beta}}-\boldsymbol{\beta}) \dot{\sim} N\left(0,[D g(\boldsymbol{\beta})]^{\prime} \widehat{\operatorname{cov}}(\hat{\boldsymbol{\beta}})[D g(\boldsymbol{\beta})]\right)
$$

and finally

$$
g(\hat{\boldsymbol{\beta}}) \dot{\sim} N\left(g(\boldsymbol{\beta}),[D g(\hat{\boldsymbol{\beta}})]^{\prime} \widehat{\operatorname{cov}}(\hat{\boldsymbol{\beta}})[D g(\hat{\boldsymbol{\beta}})]\right)
$$

So

$$
\operatorname{se}\{g(\hat{\boldsymbol{\beta}})\}=\sqrt{[D g(\hat{\boldsymbol{\beta}})]^{\prime} \widehat{\operatorname{cov}}(\hat{\boldsymbol{\beta}})[D g(\hat{\boldsymbol{\beta}})]}
$$

This can be used to get confidence intervals for probabilities, etc.

## Pointwise Cls for probability of success

```
proc logistic data=crabs1 descending;
    model y = width; output out=crabs2 pred=p lower=1 upper=u;
proc sort data=crabs2; by width;
proc gplot data=crabs2;
    title "Estimated probabilities with pointwise 95% CI's";
    symbol1 i=join color=black; symbol2 i=join color=red line=3;
    symbol3 i=join color=black; axis1 label=('');
    plot (l p u)*width / overlay vaxis=axis1;
```

Estimated probabilities with pointwise 95\% Cl's

### 5.2.3, 5.2.4 \& 5.2.5 Goodness of fit and grouping

The deviance GOF statistic is defined to be

$$
D=2 \sum_{i=1}^{N}\left\{y_{i} \log \left(\frac{y_{i}}{n_{i} \hat{\pi}_{i}}\right)+\left(n_{i}-y_{i}\right) \log \left(\frac{n_{i}-y_{i}}{n_{i}-n_{i} \hat{\pi}_{i}}\right)\right\},
$$

where $\hat{\pi}_{i}=\frac{e^{x_{i}^{\prime} \hat{\beta}}}{1+e^{x_{i}^{\prime} \hat{\beta}}}$ are fitted values.
Pearson's GOF statistic is

$$
X^{2}=\sum_{i=1}^{N} \frac{\left(y_{i}-n_{i} \hat{\pi}_{i}\right)^{2}}{n_{i} \hat{\pi}_{i}\left(1-\hat{\pi}_{i}\right)}
$$

Both statistics are approximately $\chi_{N-p}^{2}$ in large samples assuming that the number of trials $n=\sum_{i=1}^{N} n_{i}$ increases in such a way that each $n_{i}$ increases.

## Group your data

Binomial data is often recorded as individual (Bernoulli) records:

| $i$ | $y_{i}$ | $n_{i}$ | $x_{i}$ |
| :---: | :---: | :---: | :---: |
| 1 | 0 | 1 | 9 |
| 2 | 0 | 1 | 14 |
| 3 | 1 | 1 | 14 |
| 4 | 0 | 1 | 17 |
| 5 | 1 | 1 | 17 |
| 6 | 1 | 1 | 17 |
| 7 | 1 | 1 | 20 |

Grouping the data yields an identical model:

| $i$ | $y_{i}$ | $n_{i}$ | $x_{i}$ |
| :---: | :---: | :---: | :---: |
| 1 | 0 | 1 | 9 |
| 2 | 1 | 2 | 14 |
| 3 | 2 | 3 | 17 |
| 4 | 1 | 1 | 20 |

- $\hat{\boldsymbol{\beta}}, \operatorname{se}\left(\hat{\beta}_{j}\right)$, and $L(\hat{\boldsymbol{\beta}})$ don't care if data are grouped.
- The quality of residuals and GOF statistics depend on how data are grouped. $D$ and Pearson's $X^{2}$ will change!

## Comments

- In PROC LOGISTIC type AGGREGATE and SCALE=NONE after the MODEL statement to get $D$ and $X^{2}$ based on grouped data. This option does not compute residuals based on the grouped data. You can aggregate over all variables or a subset, e.g. AGGREGATE=(width).
- The Hosmer and Lemeshow test statistic orders observations ( $\mathbf{x}_{i}, Y_{i}$ ) by fitted probabilities $\hat{\pi}\left(\mathbf{x}_{i}\right)$ from smallest to largest and divides them into (typically) $g=10$ groups of roughly the same size. A Pearson test statistic is computed from these $g$ groups.

## Comments

- The statistic would have a $\chi_{g-p}^{2}$ distribution if each group had exactly the same predictor $\mathbf{x}$ for all observations. In general, the null distribution is approximately $\chi_{g-2}^{2}$ (see text). Termed a "near-replicate GOF test." The LACKFIT option in PROC LOGISTIC gives this statistic.
- Can also test logit $\{\pi(x)\}=\beta_{0}+\beta_{1} x$ versus more general model $\operatorname{logit}\{\pi(x)\}=\beta_{0}+\beta_{1} x+\beta_{2} x^{2}$ via $H_{0}: \beta_{2}=0$.

# Raw (Bernoulli) data with aggregate scale=none lackfit; 

- There are 66 distinct widths $\left\{\mathbf{x}_{i}\right\}$ out of $N=173$ crabs. For $\chi_{66-2}^{2}$ to hold, we must keep sampling crabs that only have one of the 66 fixed number of widths! Does that make sense here?
- The Hosmer and Lemeshow test gives a $p$-value of 0.73 based on $g=10$ groups. Are assumptions going into this $p$-value met?
- None of the GOF tests have assumptions that are met in practice for continuous predictors. Are they still useful?
- The raw statistics do not tell you where lack of fit occurs. Deviance and Pearson residuals do tell you this (later). Also, the table provided by the H-L tells you which groups are ill-fit should you reject $H_{0}$ : logistic model holds.
- GOF tests are meant to detect gross deviations from model assumptions. No model ever truly fits data except hypothetically.

### 5.3 Categorical predictors

Let's say we wish to include variable $X$, a categorical variable that takes on values $x \in\{1,2, \ldots, I\}$. We need to allow each level of $X=x$ to affect $\pi(x)$ differently. This is accomplished by the use of dummy variables. This is typically done one of two ways.

Define $z_{1}, z_{2}, \ldots, z_{I-1}$ as follows:

$$
z_{j}=\left\{\begin{array}{cc}
1 & X=j \\
-1 & X \neq j
\end{array}\right.
$$

This is the default in PROC LOGISTIC with a CLASS $X$ statement. Say $I=3$, then the model is

$$
\operatorname{logit} \pi(x)=\beta_{0}+\beta_{1} z_{1}+\beta_{2} z_{2}
$$

which gives

$$
\begin{array}{lll}
\text { logit } \pi(x)=\beta_{0}+\beta_{1}-\beta_{2} & \text { when } & X=1 \\
\text { logit } \pi(x)=\beta_{0}-\beta_{1}+\beta_{2} & \text { when } & X=2 \\
\text { logit } \pi(x)=\beta_{0}-\beta_{1}-\beta_{2} & \text { when } & X=3
\end{array}
$$

## Zero/One dummy variables

At alternative method uses "zero/one" dummies instead:

$$
z_{j}= \begin{cases}1 & X=j \\ 0 & X \neq j\end{cases}
$$

This is the default if PROC GENMOD with a CLASS X statement. This can also be obtained in PROC LOGISTIC with the PARAM $=$ REF option. This sets class $X=I$ as baseline. Say $I=3$, then the model is

$$
\operatorname{logit} \pi(x)=\beta_{0}+\beta_{1} z_{1}+\beta_{2} z_{2}
$$

which gives

$$
\begin{array}{lll}
\text { logit } \pi(x)=\beta_{0}+\beta_{1} & \text { when } & X=1 \\
\text { logit } \pi(x)=\beta_{0}+\beta_{2} & \text { when } & X=2 \\
\text { logit } \pi(x)=\beta_{0} & \text { when } & X=3
\end{array}
$$

## SAS example

I prefer the latter method because it's easier to think about for me. You can choose a different baseline category with REF=FIRST next to the variable name in the CLASS statement. Table 3.8 (p. 89):

```
data mal;
    input cons present absent @@;
    total=present+absent;
    datalines;
    148417066}223814464 3 5 788441126 5 1 37
;
proc logistic;
    class cons / param=ref;
    model present/total = cons;
```

## SAS output

Testing Global Null Hypothesis: BETA=0

| Test | Chi-Square | DF | Pr > ChiSq |
| :--- | ---: | ---: | ---: |
| Likelihood Ratio | 6.2020 | 4 | 0.1846 |
| Score | 12.0821 | 4 | 0.0168 |
| Wald | 9.2811 | 4 | 0.0544 |

Type 3 Analysis of Effects

| cons 1 vs 5 | 0.104 | 0.014 | 0.774 |  |
| cons 2 vs 5 | 0.097 | 0.013 | 0.727 |  |
| cons 3 vs 5 | 0.235 | 0.027 | 2.061 |  |
| cons 4 vs 5 | 0.294 | 0.018 | 4.810 |  |

## Interpretation

The model is
$\operatorname{logit} \pi(X)=\beta_{0}+\beta_{1} I\{X=1\}+\beta_{2} I\{X=2\}+\beta_{3} I\{X=3\}+\beta_{4} I\{X=4\}$
where $X$ denotes alcohol consumption $X=1,2,3,4,5$.

- Type 3 analyses test whether all dummy variables associated with a categorical predictor are simultaneously zero, here $H_{0}: \beta_{1}=\beta_{2}=\beta_{3}=\beta_{4}=0$. If we accept this then the categorical predictor is not needed in the model.
- PROC LOGISTIC gives estimates and Cls for $e^{\beta_{j}}$ for $j=1,2,3,4$. Here, these are interpreted as the odds of developing malformation when $X=1,2,3$, or 4 versus the odds when $X=5$.
- We are not as interested in the individual Wald tests $H_{0}: \beta_{j}=0$ for a categorical predictor. Why is that? Because they only compare a level $X=1,2,3,4$ to baseline $X=5$, not to each other.
- The Testing Global Null Hypothesis: BETA=0 are three tests that no predictor is needed; $\boldsymbol{H}_{0}: \operatorname{logit}\{\pi(x)\}=\beta_{0}$ versus $H_{1}: \operatorname{logit}\{\pi(x)\}=\mathbf{x}^{\prime} \boldsymbol{\beta}$. Anything wrong here? We'll talk about exact tests later.
- Note that the Wald test for $H_{0}: \boldsymbol{\beta}=0$ is the same as the Type III test that consumption is not important. Why is that?
- Let $Y=1$ denote malformation for a randomly sampled individual. To get an odds ratio for malformation from increasing from, say, $X=2$ to $X=4$, note that

$$
\frac{P(Y=1 \mid X=2) / P(Y=0 \mid X=2)}{P(Y=1 \mid X=4) / P(Y=0 \mid X=4)}=e^{\beta_{2}-\beta_{4}}
$$

This is estimated with the CONTRAST command.
